ABSTRACT

Recent interest in military VTOL/STOL aircraft employing unprepared landing sites has led to interest in the problem of landing surface erosion. Surface erosion is caused by the aerodynamic forces on ground particles existing within the flow field of an impinging jet. The inviscid flow field is discussed and the viscous ground boundary layer is analyzed utilizing both theory and available experimental data. A mathematical model of the process of entrainment of ground particles is constructed. Erosion rates in the form of erosion profiles are predicted for selected jet configuration and types of terrain. A criterion for entrainment, due to both lift and drag, was found and presented for selected distances from the jet centerline.

1. Introduction.

The increasing interest in, and use of, VTOL aircraft and other vehicles with vertically directed fans and jets, particularly in military operations, has brought about concern for the deterioration of unprepared or soft landing sites. The downwash impingement caused by these aircraft results in a radially developed viscous flow field on the ground, producing forces adequate to cause entrainment of the ground particles. The reasons for concern with this problem are numerous. In addition to possible damage to the aircraft itself and the erosion of the landing surface there are the accompanying hazards to ground personnel, damage to ground support equipment, poor visibility afforded the pilot, and the violation of the military concept of concealment. The present study was designed to construct a mathematical model of the ground erosion process to allow prediction of the initial erosion rates for various types of terrain for various nozzle velocities and geometries. Previous work [1, 14, 15, 22, 23, 25] on the problem of erosion due to downwash impingement has been primarily an experimental examination of the problem with small scale jets.

The critical mechanism in the erosion process is the interaction of the ground boundary layer and the terrain particles. An analysis of this mechanism requires an understanding of the viscous mixing problem of a finite free jet, with the inviscid flow field extending radially from the jet center line as a result of the presence of the ground plane. An analysis of the phenomenon which produces entrainment of the ground particles is basically a study of the aerodynamic forces which exist in the ground boundary layer, as they are affected both by the decaying inviscid flow field above the boundary layer and by the constraint of the

ground surface. In analyzing the boundary layer forces available theory was utilized whenever possible, but since the radially developed boundary layer runs the gamut of stagnation point flow to turbulent flow and then complete decay, there are areas for which no theory or exact solution exists. To fill these holes, experimental data were used. Where exact solutions were used for the velocity profiles within the boundary layer, verification was made with experimental results if data existed.

The analysis was restricted to single jets of uniform dynamic pressure loading and circular cross-section under "no wind" conditions shown diagrammatically in Fig. 1. An axi-symmetric boundary layer was assumed, acting over a terrain of uniform particle size and density. Table I indicates the various combinations of nozzle characteristics and radial stations that were analyzed. The prediction of erosion rates is necessarily restricted to incipient motion, since the secondary effect of random collision is not readily treated by analysis and because the constantly changing shape of the ground surface is not accounted for as a continuing process. Although this work is restricted to consideration of uniform jets only, previous experiments by Morse [23] indicate that the dynamic pressure distribution due to downwash from rotor blades and ducted fans is similar to that for a uniform jet. The uniformity of the jet or downwash appears to be a critical factor only for ratios of jet altitude to diameter, Z/D_N , less than unity.

2. History of the Problem.

The classic problem of an impinging jet on a normal surface is not new, but its application to the field of VTOL aircraft, of either rotor or jet type, has been generated only within the past several years. The problem of surface erosion resulting from impinging downwash first received attention from Kuhn [14]. Kuhn's work was experimental employing small scale test equipment to make dynamic pressure distribution surveys. An experiment was conducted by fixing the nozzle dynamic pressure and raising or lowering it over terrain of known condition. Testing was done with various types of sod, dry and wet dirt, dust, and sand. Similar experimental tests have been conducted more recently by Morse [23].

The most recent work done on this problem is that of Brady and Ludwig [26]. This work consists of extensive experiments to investigate the characteristics of the impinging uniform jet, including both the inviscid flow and the ground boundary layer. Measurements of boundary layer velocity profiles were compared with theory and showed agreement to a limited degree. Some of these experimental results have been used in support of the present work. Vidal [28] has given an insight into the aerodynamic forces existing within the boundary layer.

3. The Flow Field.

In order to consider the mechanism of particle entrainment and ground erosion, a thorough knowledge of the flow field of the impinging jet is required. This flow field can effectively be separated into three regions. The first of these regions exists regardless of the presence of the ground surface, and is the region of viscous decay immediately external to the jet nozzle. Viscous decay of a free jet is a classical problem under uniform conditions. This region is characterized by the flaring out of the jet as the jet boundary mixes viscously with the stationary field external to it. Introducing a ground surface into the flow field, normal to the jet, does not invalidate the quantitative solution of free jet decay, but restricts its extent of usefulness. Experimentation has shown that the theory of viscous decay of a free jet is adequate for the impinging jet problem for nozzle heights of greater than about eight jet diameters. Since in this work, the interest is in nozzle heights of $Z/D_N < 8$, an additional region of viscous mixing with the stationary boundary must be studied and determined, beginning with the point at which the presence of the ground surface has altered the free jet characteristics. Further study must then be made of the viscous decay of the jet after impingement on the ground plane. To date no satisfactory theoretical method exists for dealing with the entire flow region in three dimensions. This problem may be partially overcome, however, by including the viscous decay region in describing the inviscid flow field.

Knowledge of the inviscid flow field is necessitated by the requirement that the inviscid velocity existing at the upper edge of the ground boundary layer be known. The difficulty in finding a theoretical solution for this region lies in the fact that although the boundary conditions

are well defined, the location of the free streamline is not known. Three dimensional theoretical solutions of this problem are limited to approximate methods. One of these, by LeClerc [10], uses an electrolytic analog to determine the shape of the free streamline boundary. In this method the solution of the inviscid flow region was accomplished by relaxation techniques, predicting velocity and pressure distribution. Such a method of solution could be made to approach the exact solution to any desired degree of accuracy.

In the present work an exact solution of the inviscid flow field was not required. It was assumed adequate to use existing experimental data which compared favorably with the limited theoretical analyses available. In most instances it was found that the theoretical solutions were not in good agreement with the experimental data for $R/D_N < 4$. The approximate methods of predicting the characteristics of the inviscid flow region by use of an equivalent inviscid jet of greater diameter and decreasing dynamic pressure, or by replacing the jet with a cylindrical vortex sheet of constant radius extending to the ground, have proven unsatisfactory when compared with experimental data. In view of this, available experimental data were used in this work as a solution to the inviscid flow field. Fig. 2 shows the result of empirical equations fitted to these data.

The third flow region is that of the ground boundary layer. A thorough knowledge of this region was most important to this work as the ground particles are predominately immersed in the boundary layer, and the mechanics of particle movement originate with the aerodynamic forces resulting from the characteristics of the boundary layer.

4. The Ground Boundary Layer.

The key to the entire analysis of ground erosion is the mathematical model used for the boundary layer. Sound theoretical analysis of the boundary layer was used in this study when possible. Experimental results were used whenever the theory was non-existent or was in large disagreement with these results. For effective analysis the boundary layer may be divided into four regions. The first is the stagnation area boundary layer existing adjacent to the jet center line and extending to $R/D_N = .5$ or to a station directly under the original free jet boundary. This area is laminar for the conditions investigated. The solution of this region utilized the Himenez solution [18] for the uniform impinging jet on a perpendicular wall. Experimental results were not available for this region, so that the validity of this solution is not verified but was assumed. The Himenez solution in three dimensional flow, developed by Homann [18] is an exact solution utilizing the Navier-Stokes equations for axisymmetric flows. The solution was developed explicitly for stagnation conditions and the velocity profiles resulting from this have been employed to $R/D_N = 0.5$. The nondimensional velocity profile is shown in Fig. 3.

The second region is the laminar boundary layer extending from the edge of the original jet boundary to the radial station at which transition begins. A complete method of solution for this laminar region, by Smith [19], is well verified by experiment for $Z/D_N = .5$ [26], but gives little insight as to the limit of the laminar region and the beginning of transition. This point has been approximated by Brady and Ludwig [26] from considerations of neutral stability of the laminar boundary layer. A Reynolds Number at which the boundary layer becomes neutrally

stable can be determined [18] and may be converted to a jet nozzle Reynolds Number as a function of $(R/D_N)_{CRIT.}$ On this basis the boundary layer becomes unstable at $R/D_N \approx 1.0$ for the jet velocities and nozzle diameters analyzed in this work. In view of this, and the fact that the inviscid velocity generally reaches a peak in the vicinity of $R/D_N = 1.0$ (Fig. 2), the beginning of transition was taken to be $R/D_N = 1.0$.

The transition region is even more difficult to define. Since fully turbulent flow exists theoretically when the pressure gradient on the ground surface is essentially zero, it was assumed that the transition region extended to the station where the pressure gradient could be taken to be negligible. Fig. 4 shows the static pressure distribution near the ground taken from an electrolytic analogy of the entire flow field [10]. The station at which the gradient, $\partial(\frac{P_s - P_a}{\frac{1}{2} \rho V_j^2}) / \partial x$, was taken to be zero was $R/D_N = 2.0$. For the laminar and transition regions of the boundary layer experimental results were used to form the velocity profiles. This data, collected by Brady and Ludwig [26] for a limited range of jet velocities indicate that the non-dimensional velocity profile was almost completely independent of the jet velocity. The measurements were taken at nozzle heights in the range $Z/D_N = 0.5$ to 4.0 at four locations and for the radial range of $R/D_N = .5$ to 1.33 at six different stations. These twenty-four configurations are assumed to be fairly representative of the laminar and transition regions and are shown in Figs. 5a through 5h. For purposes of computation, curves were fitted to each group of data.

The fourth region in the boundary layer is the turbulent regime. It was assumed that this region begins at $R/D_N = 2$ as this is the

station at which the pressure gradient is assumed negligible. A limited amount of work has been done on theoretical solutions of turbulent boundary layers. One of these that appears applicable to the impinging jet is that of Glauert [7]. This single solution for velocity profiles in the turbulent boundary layer, assumed valid to $R/D_N = 4$, which is the radial limit of the analysis, has been verified by experimental results at $R/D_N = 1.33$ [26]. The uncertainty as to the characteristics of flow decay limit further extension of the analysis.

Glauert set up the boundary layer equations and found a similarity solution in which the form of the velocity distribution across the jet does not vary along its length. The solution is dependent upon the assumption of an effective eddy viscosity as required to satisfy the law due to Blasius for flow in a pipe as well as Prandtl's hypothesis for free turbulent flow. The first solution is considered to be valid near the ground surface, and the second to be valid above some determined distance from the ground surface. Fig. 6 shows these results in the form of a velocity profile, for the radial distances and nozzle heights considered in the present work. It was found that the shape of the velocity profile was essentially independent of both the radial distance and the nozzle height, but is dependent upon the nozzle Reynolds Number.

The turbulent region is characterized by a velocity profile which approaches a maximum, U_{max} , with increasing y and then decreases with further increase in y . As is shown in Fig. 1 it is expected that the turbulent boundary layer will continue to grow as long as there exists an inviscid upper boundary. Since very little attention has been given to this phenomenon of flow decay, and because of the nature of the turbulent solution, a fictitious boundary layer thickness is assumed for

this region. This is defined to be the thickness that exists at $U = U_{\max}$. It was found that the nature of this assumption does not affect the overall results appreciably.

5. Analysis of Aerodynamic Forces Within the Boundary Layer.

The ground boundary layer is a non-uniform flow that is characterized by a large velocity gradient or shear layer extending over a large portion of the thickness. In addition, the ground surface or wall boundary at the base of the flow forms a constraint on the streamlines as they attempt to pass beneath an obstacle bedded in the ground surface.

There are three distinct forces that exist within the boundary layer. These are: 1) Drag due to the horizontal velocity component of the flow; 2) lift due to the proximity of the wall; and 3) lift due to the velocity gradient in the flow. There is no theory available which deals with this problem in general. Therefore it was necessary to piece together an approximate theory for each of the various forces.

Drag Force.

The drag force was the easiest to account for. To simplify the analysis in a non-uniform flow, a strip analysis was made in which the spherical particle was divided into a number of layers and it was assumed that a uniform flow acted upon each layer. Knowing the velocity of the flow on each layer, from the velocity profile, the force on each layer and the summation of horizontal forces were developed. The calculation of the total drag force employed the drag coefficient of cylindrical bodies measured by Hoerner [9]:

$$N_R < 100$$

$$C_D = 30. / N_R^{.699}$$

$$100 < N_R < 10^4$$

$$C_D = 1.44 / N_R^{.0396}$$

$$N_R > 10^4$$

$$C_D = 1.18$$

In addition to the drag force the skin friction force was calculated for each layer and summed for the particle. The friction force, a result of a minute boundary layer effect on the particle itself, was relatively small but in some cases significant. For spheres in low Reynolds Number flows the skin friction coefficient can be approximated by:

$$C_F = .664 / (N_R)^{1/2}$$

The tendency of the velocity gradient to cause a moment on the particle was neglected.

Lift Due to Wall Proximity.

Theories accounting for the effect of a wall constraint in non-uniform flow do not exist, but this effect was estimated using the existing theory for uniform flow [12]. The effect of the ground surface constraint is to distort the flow over the sphere, crowding the streamlines, causing a negative lift force. The theory is based on kinetic energy considerations, maintaining equilibrium on a sphere in the presence of a wall. For a sphere, in a flow parallel to the wall, an upward force is required to maintain equilibrium, indicating that the sphere must be attracted to the wall.

The method of calculation of this lift force was similar to that of drag. The strip approximation method was used to determine an average local velocity over a particular strip. It was then assumed that this average local velocity was that existing in the vicinity of the stagnation

point, realizing that the stagnation point is shifted toward the region of higher velocities. The lift then becomes a function of the sphere size and the average local velocity, for a particle bedded on the ground plane. The kinetic energy of a sphere in a moving fluid near an infinite fixed wall can be approximated by a first order solution [12]:

$$T = \frac{1}{2} (A V_L^2 + B U_L^2)$$

where:

$$A = \frac{1}{2} m_a (1 + \frac{3}{8} r^3 / y^3)$$

$$B = \frac{1}{2} m_a (1 + \frac{3}{16} r^3 / y^3)$$

m_a = mass of fluid displaced by the sphere.

From Lagrange's equation for equilibrium:

$$d/dt (\partial T / \partial \dot{x}) - \partial T / \partial x = 0$$

If the sphere is to be maintained in equilibrium, the result is a force exerted on the sphere:

$$F_x = d/dt (\partial T / \partial \dot{x}) - \partial T / \partial x$$

$$F_y = d/dt (\partial T / \partial \dot{y}) - \partial T / \partial y$$

Making the substitutions, the force exerted on the sphere in the y or vertical direction becomes:

$$\begin{aligned} F_y &= d/dt (\partial T / \partial V_L) - \partial T / \partial y \\ &= d/dt (A V_L) - \partial / \partial y (\frac{1}{2} A V_L^2 + \frac{1}{2} B U_L^2) \end{aligned}$$

$$F_y = A V_L - (-1/2 V_L^2 9/16 m_a r^3 / y^4 - 1/2 U_L^2 9/32 m_a r^3 / y^4)$$

Assuming that $V, \dot{V} \ll 1$.

$$F_y = 9/64 U_L^2 m_a r^3 / y^4$$

where:

$$m_a = \rho_a 4/3 \pi r^3$$

we get:

$$F_y = 3/16 \rho_a U_L^2 \pi r^6 / y^4$$

Assuming that the particle is very close to the ground such that;

$$y - r \ll 1$$

or

$$y \approx r$$

the lift due to the wall constraint becomes:

$$L_w = -3/16 \rho_a U_L^2 \pi r^2$$

For the strip analysis, summation yields:

$$L_w = (-3/16 \rho_a \pi r^2 \sum_n U_{Ln}) / n$$

Lift Due to Velocity Gradient.

There have been a number of theoretical studies of the effects of velocity gradients or shear on aerodynamic forces. Most of these, however, deal either with an unbounded flow or two dimensional flow. In comparing two dimensional solutions with three dimensional solutions it

was noted that the difference is a term in the three dimensional solution describing the lateral component of flow. For the axi-symmetrical case dealt with here, this component was assumed negligible. A solution for non-uniform flow on cylinders by Murray and Mitchell [13] was employed in conjunction with a strip analysis.

In the strip analysis, the particle was divided into layers of circular cylinders situated such that their centers formed a line perpendicular to the flow. Beginning with the final result of Murray and Mitchell, the dimensionless shear velocity on each cylinder was found to be:

$$\begin{aligned}
 g' = & - \left\{ \sin \theta \left[\cosh (\sin \theta) - \frac{1}{N} \sinh (\sin \theta) \right] \right. \\
 & + \frac{2}{N} \sum_{n=1}^{\infty} (-1)^n \frac{I_{2n}(1)}{K_{2n}(1)} K'_{2n}(1) \cos (2n\theta) \\
 & \left. + 2 \sum_{n=0}^{\infty} (-1)^{n+1} \frac{I_{2n+1}(1)}{K_{2n+1}(1)} K'_{2n+1}(1) \sin (2n+1)\theta \right\}
 \end{aligned}$$

where:

$$K'_{2n}(1) = \frac{d}{da} [K_{2n}(a)]_{a=1}$$

$$\begin{aligned}
 K'_{2n}(1) = & \frac{1}{2} \sum_{r=0}^{n-1} \frac{(-1)^r (n-r-1)!}{r!} (n-2r)(2)^{(n-2r-1)} (-2) \\
 & + (-1)^{n+1} \sum_{r=0}^{\infty} \frac{(n/2+r)(1/2)^{(n+2r-1)}}{r! (n+r)!} \cdot \\
 & \left\{ \log \frac{1}{2} - \frac{1}{2} [\psi(r+1) + \psi(n+r+1)] \right\}
 \end{aligned}$$

$$+ (-1)^{n+1} \sum_{r=0}^{\infty} \frac{(\frac{1}{2})^{n+2r}}{r! (n+r)!}$$

and

$$\begin{aligned}\Psi(1) &= \text{Euler's Constant} \\ &= 0.57721567\end{aligned}$$

The dimensional shear velocity is given by:

$$g = g' U_L$$

which is of the form (when squared):

$$g^2 = U_L^2 (A^2 + B^2 + C^2 + 2AB + 2AC + 2BC)$$

Where:

$$\begin{aligned}A^2 &= \sin^2 \theta [\cosh^2 (\sin \theta - 2/N \cosh (\sin \theta) \cdot \\ &\quad \sinh (\sin \theta) + 1/N^2 \sinh^2 (\sin \theta)]\end{aligned}$$

$$B^2 = 4/N^2 \left[\sum_{n=1}^{\infty} (-1)^n \frac{I_{2n}(1)}{K_{2n}(1)} K'_{2n}(1) \right]^2 \left[\sum_{n=1}^{\infty} \cos 2n\theta \right]^2$$

$$C^2 = 4 \left[\sum_{n=0}^{\infty} (-1)^{n+1} \frac{I_{2n+1}(1)}{K_{2n+1}(1)} K'_{2n+1}(1) \right]^2 \left[\sum_{n=0}^{\infty} \sin (2n+1)\theta \right]^2$$

$$2AB = 4/N \left[\sum_{n=1}^{\infty} (-1)^n \frac{I_{2n}(1)}{K_{2n}(1)} K'_{2n}(1) \cos 2n\theta \right] \cdot$$

$$\sin \theta [\cosh (\sin \theta) - 1/N \sinh (\sin \theta)]$$

$$2AC = 4 \left[\sum_{n=0}^{\infty} (-1)^{n+1} \frac{I_{2n+1}(1)}{K_{2n+1}(1)} K'_{2n+1}(1) \sin (2n+1)\theta \right] \cdot$$

$$\sin \theta [\cosh (\sin \theta) - 1/N \sinh (\sin \theta)]$$

$$z_{BC} = 8/N \left[\sum_{n=1}^{\infty} (-1)^n \frac{I_{2n}(1)}{K_{2n}(1)} K'_{2n}(1) \cos 2n\theta \right] \cdot$$

$$\left[\sum_{n=0}^{\infty} (-1)^{n+1} \frac{I_{2n+1}(1)}{K_{2n+1}(1)} K'_{2n+1}(1) \sin (2n+1)\theta \right]$$

U_L is the local velocity at the center of each cylinder, and I , K and K' are Bessel functions of the first and second kind, and the derivative of the second kind respectively. N is a flow parameter dependent upon local velocity, radius of the cylinder and the vorticity at the stagnation point, and is defined as: $N = U_L / \omega_0 r_c$. The determination of the flow parameter was approximated since the stagnation point on each cylinder could not be known in advance of the calculations. In order to keep the shear velocity in the direction it was known to flow, a lower bound of $N = 1$ could be established. If ω_0 and U are evaluated at the geometric centers of the cylinders, experimentation has indicated an upper bound of $N = 3$ [13]. After analyzing the computed results of shear velocity with values of N ranging from 1.1 to 10, a value of $N = 1.5$ was accepted as being representative of the physical model.

Having found the shear velocity the lifting force due to shear effect was calculated for each cylinder and summed over the particle. The resulting expression is:

$$L_s = \sum_n -b r_c \rho / 2 \int_0^{2\pi} (U_{Ln}^2 - q_n^2) \sin \theta d\theta$$

Where:

r_c = radius of cylindrical strips

b = width of strip

n = number of strips

Noting that:

$$\int_0^{2\pi} U_h^2 \sin \theta d\theta = 0$$

We have:

$$L_S = \sum_n b r_c \frac{1}{2} U_h^2 \int_0^{2\pi} (A^2 + B^2 + C^2 + 2AB + 2AC + 2BC) \sin \theta d\theta$$

In evaluating the integral we have:

$$\int_0^{2\pi} 2BC \sin \theta d\theta = 8/N \left[\sum_{n=1}^{\infty} (-1)^n \frac{I_{2n}(1)}{K_{2n}(1)} K'_{2n}(1) \right]$$

$$\left[\sum_{n=0}^{\infty} (-1)^{n+1} \frac{I_{2n+1}(1)}{K_{2n+1}(1)} K'_{2n+1}(1) \right] \left[\sum_{n=1}^{\infty} \int_0^{2\pi} \cos 2n\theta \sin \theta d\theta \right]$$

$$\left[\sum_{n=0}^{\infty} \int_0^{2\pi} \sin (2n+1)\theta \sin \theta d\theta \right] = 0$$

Since the last two integrals are identically zero. Further we may write:

$$\begin{aligned} \int_0^{2\pi} A^2 \sin \theta d\theta &= \int_0^{2\pi} \sin^3 \theta \cosh^2(\sinh \theta) d\theta \\ &- \frac{2}{N} \int_0^{2\pi} \sin^3 \theta \cosh(\sinh \theta) \sinh(\sinh \theta) d\theta \\ &+ \frac{1}{N^2} \int_0^{2\pi} \sin^3 \theta \sinh^2(\sinh \theta) d\theta \end{aligned}$$

$$\int_0^{2\pi} A^2 \sin \theta d\theta = -2/N \int_0^{2\pi} \sin^3 \theta \cosh(\sin \theta) \sinh(\sin \theta) d\theta$$

Since the first and last integrals are identically zero.

Due to the complexity of the above expressions and the difficulty of integration, it was desired to check this method with another method [29] of a much more approximate nature for calculating the lift due to shear.

The alternate method of calculating lift assumes that the previously discussed lift due to the ground surface constraint is negligible and that the lift forces on the particle can be estimated by using the solution of Hall 8 for a sphere in a two dimensional uniform shear flow. In addition, the approximate method assumes that the sphere rests on a bed of spheres of the same diameter and that the pressure on the bed is the ambient stream static pressure. The lift coefficient then becomes simply a function of the local slope of the velocity profile, , the local velocity on the sphere, and the radius of the sphere. In view of the many restrictions placed on this solution it was used only as an order of magnitude check on the other solutions. Fig. 7 shows a comparison of the two solutions.

6. Particle Entrainment and Incipient Erosion Rates.

Only a few of the possible types of terrain to which a mathematical analysis of the erosion rates might be practically applied, were investigated. Uniform particles ranging in size from .003 in. to .125 in. in diameter were investigated. The smallest sizes represent loose dirt and the larger diameters represent sand or sandy gravel, with .125 in. being representative of small gravel type rock. It was assumed that all terrain was without any moisture content. The densities of the particles ranged from 75 lb/ft³ for loose dirt to 125 lb/ft³ for gravel. Table II lists the various terrain particles analyzed.

There are three possibilities for entrainment of the ground particle. The first is that it may have enough lift force on it to be lifted directly from the ground surface into the free stream. The second is that after rolling motion is started due to the drag force, it may be able to gain the additional lift required for entrainment in the free stream. The third is that with many particles rolling at different velocities the random collision of particles that follows will bounce some of them into the inviscid stream. Only incipient motion is within the scope of this work, hence it was assumed that any particle which was moved contributed to the erosion rate.

The net drag force and the net lift force, including both mechanisms of lift, were computed for each of the particles, at each of thirteen radial stations on the ground surface for each of the nozzle configurations studied. To calculate the initial net drag force, the previously mentioned ground surface model of nested particles was assumed using a coefficient of static friction of .

7. Results and Conclusions.

The particle size criteria for lifting entrainment and drag entrainment are shown in Figs. 8, 9, and 10 in which the particle size is plotted versus a load parameter at various stations with jet velocity and jet height as parameters. The load parameter is defined as the particle density divided by the dynamic pressure in the free stream. The lift entrainment criterion predicts that an optimum particle size, the particle size most prone to entrainment, exists for all radial stations and that the critical density increases with radial distance to a certain R/D_N . The optimum particle size for lift entrainment occurs because particles smaller than the optimum are affected by much smaller velocities, and particles larger than optimum are affected more by a flow region where the shear gradient, $\partial U / \partial y$, approaches zero.

The drag criterion indicates that extremely small particles of 0.02 in. diameter or less, up to very high densities will roll on the ground (see Fig. 8). As the particle size is increased the possibility of rolling decreases rapidly up to a particle diameter of 0.03 in. at which size the tendency to roll increases again, since the larger velocities in the boundary layer begin to act on the particle, until an optimum diameter of approximately 0.06 in. is reached. For radial distances less than $R/D_N = .1$, velocities in the boundary layer are not sufficient to move large particles of high density. The range of optimum size particle for drag entrainment of approximately .03 to .09 is consistent for all radial stations. It is of particular significance that the range of optimum particle diameter for both lift and drag is very nearly equal to the boundary layer thickness at the particular radial station being considered.

The incipient erosion rates for selected densities, particle sizes, and nozzle configurations are shown in Figs. 11 and 12. These are found by combining as vectors the incipient horizontal and vertical accelerations of the particles. This was assumed to be proportional to the incipient erosion rate. The erosion rate, normalized by the maximum rate, is plotted versus the nondimensional radial distance. For all configurations and particles the erosion profile is maximum in the area $.5 < R/D_N < 2.0$. The maximum erosion for larger particles occurs near $R/D_N = 1$, and then drops off sharply with increased radial distance. As the particles become smaller a maximum erosion occurs closer to the perimeter of the jet nozzle and a second maximum begins to occur at $R/D_N \approx 1.3$. This occurs after the transition region has begun to form and where the onset of turbulence can affect the particles. Fig. 13 shows the incipient rate of lift entrainment by itself and indicates that, in general, the shape of the erosion profile can be attributed to the lift forces.

The results shown in the graphs represent only a few configurations selected from the large amount of data collected. In viewing all of the results and comparing the many combinations of configurations, it was found that the variation of ground erosion rates was principally a function of the dimensionless radial distance from the jet centerline and the size of the particle for a given nozzle height, Z/D_N . The erosion rate was nearly proportional to the particle density except near the stagnation point, where the erosion rates were very small.

From these results it may be concluded that for ground particles of less than .04 in. diameter the incipient erosion rate has two maximum points. One in the vicinity of the perimeter of the jet nozzle, and the

second at a radial distance approximately two diameters from the stagnation point. For very small particles and low jet velocities the second maximum is the most significant. In all other cases where two maximum points exist, the first is the most significant. For ground particles whose diameters are greater than .04 in. a single maximum point exists near the perimeter of the jet nozzle. As the particle size increases the influence of the turbulent region decreases.

It was concluded that particles of approximately .02 in. diameter or less would entrain due to drag even at very high densities or very low velocities. For particles larger than approximately .02 in., an optimum size of approximately .06 in. exists up to radial distances of four nozzle diameters for drag entrainment. An optimum particle size most susceptible to entrainment due to lift exists in the range of .07 to .12 in. diameter for radial distances up to four nozzle diameters.

Also, it may be concluded that varying the nozzle diameter had very little effect on the dimensionless erosion rate; hence in the final analysis the nozzle diameter was not considered as a parameter. Moreover, while the actual erosion rates were approximately linearly dependent upon the jet velocity, the dimensionless erosion profile appeared to be independent of jet velocity, with the exception of the order of importance of the maximum points.

APPENDIX

FORTTRAN PROGRAMS

LIFT FORCES:

Input.

Program is generated from the polynomials describing the velocity profiles of the boundary layer, for various radial stations.

MM	Number of terms of the polynomial
PCOZ	Coefficients of the polynomial
QSH	Nondimensional shear velocity
VJ	Jet velocity
DN	Nozzle diameter
RG	Radial distance from jet centerline
ZG	Nozzle height above ground
YHVX	Distance to have maximum velocity in turbulent boundary layer
VMX	Maximum velocity in turbulent boundary layer

Intermediate Results and Output

DP	Particle diameter
VI	Inviscid velocity
YND	Nondimensional distance above ground
XND	Nondimensional roots of velocity profile polynomial
DNS	Particle density
DVX	Derivative of polynomial
SDVX	Slope of velocity profile -
DUDY	Slope of velocity profile -
FLSC	Shear lift (cylinder method)
SLFT	Shear lift (sphere method)
PLFT	Lift due to wall constraint
PLAC	Acceleration of particle in vertical direction

Subroutine Root finds the roots of the velocity profile polynomial
